Abstract

Background: Ultrasonography (US) is the cheaper and non invasive modality to determine Achilles tendon. Prone position is the standart position of Achilles tendon US. However, it is a discomfort for an uncooperative patient and a difficult technique too. The erect position is an alternative technique of Achilles tendon US. The goal of this study is to compare the erection as an alternative position with prone as a standart position.

Material and Methode: The patient who had an injury or any inflammation process of Achilles tendon were excluded. The patient underwent two positions of Achilles tendon US, 900 and dorsoflexi. Longitudinal axis measured tendon thickness and a transversal axis which covered a cross-sectional area of the tendon.

Result: From all the 21 patients coming, 13 patients were males (61,9%), and eight patients were females (38,1%). The mean of tendon thickness and cross-sectional area in 900 prone positions were 4,24±0,24 mm, 30,08±2,86 mm, respectively. The mean of tendon thickness and cross-sectional area in 900 erect positions were 4,27±0,23 mm, 31,36±2,19 mm, respectively. There was no anisotropy effect during longitudinal axis examination.

Conclusion: We found that there were no significant differences between a prone and erect position (p<0.05). The erect position could be an alternative position, uncooperative patient in particular, without reducing the diagnostic value.

Keywords: Achilles tendon the US, erect position, prone position, tendon thickness, cross-sectional area

INTRODUCTION

Achilles tendon is the largest and strongest tendon in the human body, but it is also mostly affected by trauma. Trauma to the Achilles tendon is usually associated with poor flexibility and stabrility of ankle and also over the use of them.

Currently, Ultrasound (US) musculoskeletal is the choice for the patient as a supporting diagnostic besides Magnetic Resonance Imaging (MRI), because

Ultrasound (US) musculoskeletal is cheap, not invasive and it can be done quickly. In clinical practice, ultrasound musculoskeletal is widely accepted and developed in Europe and United States. Standard position for assuring the ultrasound (US) of the Achilles tendon is anatomically in a prone position or standard 90°. If this position is in the relatively long period, it will cause discomfort, distress to the patient and difficult in technique. The patients will suffer those bad cause; moreover, to the patients with certain clinical conditions.

MATERIALS AND METHODS

There are a total of 21 healthy patients being tested for their US Achilles tendon at Airlangga University Hospital. Every patient has examined for Achilles tendon US in prone position anatomically (90°) and also dorsoflexion and in erect position anatomically (90°) and also dorsoflexion. The inclusion criteria are that the patients: have never been experienced in inflammation, a trauma or structural abnormalities of the ankle area, the patients can be examined of US in the position of both prone and erect. The US examination used a US device of Siemens brand, Acuson X150 with a linear probe. Every position was done US examination by measuring the tendon thickness, transversal axis, wide and longitudinal axis. The data were analyzed by using a comparison test.

Examination technique with prone position.

All patients are tested for their US Achilles tendon in a 90° prone position and a dorsoflexion. At that 90° positions, the patient's feet were hanging over the end of the examination table, and the position of feet dorsoflexion rested on the examination table (Figure 1). The probe used is a linear probe with its depth of 4 mm, the probe placement area is parallel to the medial malleolus. The Achilles tendon will then be examined in a longitudinal axis, as a result of ultrasound, it is to be measured its tendon thickness which is also called diameter of Achilles tendon anteroposterior, the measurement is started by drawing a straight line from the upper limit of the tendon to the lower limit of the tendon. In the transverse incision, the extent area is measured, or it is called the circumference of a circle of the Achilles tendon (Figure 2, 3, 4, 5). The measurement using the calliper menu – starts the area from the outer boundary line of the surrounding Achilles tendon.

Examination techniques in a standing (Erect) position.

It is similar to the prone position that all patients will be US checked at the 90° position and the dorsoflexion. In the 90° standard standing positions, the samples are instructed to stand upright on the step ladder or the top of the step ladder (Figure 1). The next step is to place the probe in a longitudinal slice to examine the Achilles tendon thickness and to place the probe on the transversal slice to be examined the tendon extent area (Figure 6, 7, 8 and 9).

Statistical Analysis.

The consecutive (list of) data were displayed in the form of an average following its standard deviation. Data variation on the size of thickness and wideness of the Achilles tendon were analyzed with the independent variables, namely: the 90° standard prone positions, the dorsoflexion prone position, the 90° standard standing positions, and the standing dorsoflexion position. The data were tested using independent t test. Differences were considered significant when P <0.05. The data were processed using SPSS 16.0 for Windows.
RESULT AND DISCUSSION

Of all 21 patients who underwent the test consisted of 13 men (61.9%) and eight women (38.1%) with the mean of 21.9 y.o ± 2.143. The mean of height and weight were 165.5 cm ± 7.776 dan 63.38 kg ±12.294, respectively. In this study were not studied due to the effect of height and weight on the measurement results of the Achilles tendon. The result of the Achilles tendon measurement is shown in Table 1. The mean value or mean of the extent area of the Achilles tendon in the 90° standard prone positions is 30.08 ± 2.86 mm, while in the 90° standard standing position, the values obtained are 31.36 ± 2.19 mm. The mean value or mean of the extent area of the Achilles tendon in the dorsoflexion prone position is 31.51 ± 2.33 mm, while in a dorsoflexion standing position the value obtained is of 32.08 ± 2.28 mm.

The Achilles tendon is the largest and the strongest tendon in the body. It is formed by the combined tendon of the gastrocnemius and soleus muscles (triceps surae). The Achilles tendon begins at the junction between gastrocnemius and soleus tendon in the middle of the calf.

Regarding morphology, normal Achilles tendon thickness should be no more than 8 mm in the dimensions of anteroposterior (AP), it becomes proximally thick and slightly tapers along the third distal for insertion on the calcaneal tubercle. The normal retrocalcaneal caudex should produce a radiolucent anterior to the distal fibers of insertion of the Achilles tendon which extends at least 2 mm below the superior surface of the calcaneus.

On the examination of the Achilles tendon, the previous patient is in a lying face downward, or in a prone, i.e. the patient’s legs are dangling at the end of the examination table. The scan is performed on the Achilles tendon subsequently with a linear probe from the myotendinous junction until insertion calendar on the transversal and longitudinal area. The scanning is set at the medial level of the malleolus with the ultrasound probe is situated perpendicular to the Achilles tendon. In addition to the standard position, the dorsoflexion position will straighten the Achilles tendon to avoid anisotropy. The anisotropy is seen as an hypo-echoic focal area when the angle of the probe was not in 90 degrees on the structure depicted. It is easily found when the results of the Achilles tendon picture are as if the hypo-echoic which indicate pathological features up under the tendon.

In some people or certain conditions, the default position will cause the patient discomfort, and technically it will be difficult to be done as if there were a respiratory problem.

Modification of the ultrasound examination technique of the Achilles tendon is a new kind of research; there has been no similar study comparing the positioning techniques of Achilles tendon ultrasound. The Achilles tendon size obtained from this study is a new kind of innovation because there is no specific reference to the size of the Achilles tendon for the Southeast Asian, especially Indonesian. The previous study by Pang in 2006 at The Hong Kong Polytechnic University discussed the size of thickness, wide area, and length of the Achilles tendon by age, weight and use of the dominant foot technically it will be difficult to be done as if there were a respiratory problem.

Pang et al. found that the thickness and area wideness of the tendon with a lifespan of samples of 20 to 29 years, is 5.14 mm ± 0.57 and 57.80 mm2 ± 11.61. While this study reveals that the Achilles tendon thickness on the 900 standards prone position is 4.24 mm ± 0.24, the area wideness of the Achilles tendon is 30.08 mm2 ± 2.86. The result difference of the Achilles tendon measurement obtained by the research may have been influenced by specific factors, namely: race factors, height, weight, and foot activity which are frequently used.

Of the twenty-one samples being studied consisted of 13 men (61.9%) and eight women (38.1%) with a mean of 21 years of age. The data analysis of the measurement using the independent t-test showed the thickness and the size of the prone position of the Achilles tendon, the 900 standard standing positions and dorsoflexion had resulted in the same value of P>0.05. This value means that there is no significant difference in the results. The examination results of the US Achilles tendon in both prone and standing position shows no description of anisotropy.

Due to no significant difference of thickness measurement results and area wideness of the Achilles tendon in a prone position and standing; moreover, in both standard and dorsoflexion, the standing position can then be used as an alternative technique to test the Achilles tendon ultrasound.

**CONCLUSION**

Modification technique of testing the Achilles tendon ultrasound in a standing position reveals no significant difference of the measurement results compared to a standard position, prone. Thus, the standing position becomes the alternative position of measurement technique on Achilles tendon US for the sonographer, doctor of radiology in improving patients’ comfort without affecting the diagnostic value.
